ABSTRACT

The vegetation component in climate models has advanced since the late 1960s from a uniform prescription of surface parameters to plant functional types (PFTs). PFTs are used in global land-surface models to provide parameter values for every model grid cell. With a simple photosynthesis model we derive parameters for all site years within the Fluxnet eddy covariance data set. We compare the model parameters within and between PFTs and statistically group the sites. Fluxnet data is used to validate the photosynthesis model parameter variation within a PFT classification.

Our major result is that model parameters appear more variable than assumed in PFTs. Simulated fluxes are of higher quality when model parameters of individual sites or site years are used. A simplification with less variation in model parameters results in poorer simulations. This indicates that a PFT classification introduces uncertainty in the variation of the photosynthesis and transpiration fluxes. Statistically derived groups of sites with comparable model parameters do not share common vegetation types or climates.

A simple PFT classification does not reflect the real photosynthesis and transpiration variation. Although site year parameters give the best predictions, the parameters are generally too specific to be used in a global study. The site year parameters can be further used to explore the possibilities of alternative classification schemes.

1. Introduction

The specification of the land surface component of climate models has evolved through four major steps over the past four decades. The first generation in the late 1960s had a uniform prescription of surface parameters (see reviews by Sellers et al., 1997; Pitman, 2003), while the second generation in the 1980s introduced the concept of plant functional types (PFTs) to describe the effects of spatially varying vegetation on the surface energy balance (e.g. Sellers et al., 1986; Dickinson et al., 1986). In the third generation of models vegetation is simulated dynamically rather than being prescribed (Friend and Cox, 1995; Sellers et al., 1997; Foley et al., 1998; Woodward et al., 1998; Cox et al., 2000), while

the latest models couple vegetation dynamics to the carbon and nitrogen cycles (Thornton et al., 2009; Yang et al., 2009; Zaehle and Friend, 2010), and include processes for emissions of reactive trace gases, vegetation–fire interactions and crop–biogeochemistry interactions (Arneeth et al., 2010).

To run these land-surface models globally, it is necessary to provide parameter values for every model grid cell, and typically this is done by assigning a unique parameter set for each PFT. Early PFT classifications were developed for calculating the surface energy and water balance and were largely based on broad classes of vegetation. Later these PFTs were applied to deduce the carbon balance of the land surface, even though a number of carbon cycle processes might not run parallel to the energy and water processes upon which the original classifications were based. More recently PFT classifications have been derived following either a deductive or an inductive approach (Woodward and Cramer, 1996). Examples of PFT classifications derived using the deductive approach are

presented by Box (1996), Bonan et al. (2002) and Sitch et al. (2003). Here the criteria for PFTs are based on climatic limitations such as temperature, precipitation and length of the growing season. These PFTs are subjectively classified based on a general understanding of processes. With the inductive approach (Woodward and Cramer, 1996) PFTs are derived from sets of observations or experimental results e.g. through statistical clustering with climatic variables and vegetation traits (Chapin et al., 1996; Wang and Price, 2007).

The assumption that parameters in carbon exchange models can conveniently be allocated to PFTs appears to contradict observed gradual transitions between different ecosystem types. Kleidon et al. (2007) show that the strict separation of vegetation into less than eight PFTs may lead to artificial multiple steady-states in a model of the Earth's climate–vegetation system depending on the number of PFTs used. Measurements on individual leaves indicate a gradual transition in vegetation characteristics. Leaf traits are inter-related e.g., maximum photosynthetic capacity, maintenance respiration, nitrogen concentration, leaf life span and specific leaf area (ratio of leaf surface area to leaf mass) (Reich et al., 1997; Bonan et al., 2002; Meinzer, 2003; Wright et al., 2004). Harrison et al. (2010) therefore suggest using these continuous traits for the development of a new vegetation classification.

On the global scale it is a challenging task to provide sufficient data for a complete PFT classification, because a large number of observations are needed for each PFT (Wang and Price, 2007). Many studies have used eddy covariance data from Fluxnet (a global network of sites), showing the variation in carbon and water fluxes between vegetation types and along climate gradients (e.g., Baldocchi, 2008; Law et al., 2002; Friend et al., 2007; Luysaert et al., 2007; Stöckli et al., 2008; Stoy et al., 2009; Beer et al., 2009; Yuan et al., 2009; Williams et al., 2009). The eddy covariance data can also be used to derive model parameters (e.g., Reichstein et al., 2003b; van Dijk and Dolman, 2004; Knorr and Kattge, 2005; Raupach et al., 2005; Owen et al., 2007; Richardson et al., 2007; Wang et al., 2007; Thum et al., 2008). However, hardly any of these studies have attempted to derive model parameters for key carbon cycle processes such as photosynthesis for the full set of data.

This study uses a simple vegetation model to derive the parameters for all site years and vegetation types within the Fluxnet database. We compare the set of model parameters within and between PFTs and group the sites statistically. We combine the deductive and inductive PFT classifications to give insight into the variation of model parameters. We address the following specific questions: (1) what is the variability of parameter values for a set of conventionally defined PFTs, (2) how well are fluxes simulated using parameter values for each PFT compared to using site-calibrated values at diurnal, seasonal and annual time scales, (3) if using mean or median values provides unsatisfactory results, is it sufficient to refine the classification scheme and, (4) if this is unsatisfactory, does a cluster analysis of parameters provide a satisfactory solution?

2. Methodology

2.1. Model description

The photosynthesis model of Farquhar et al. (1980) is widely used in vegetation models (e.g., Sellers et al., 1996; Arora, 2002; Sitch et al., 2003; Krinner et al., 2005; Rayner et al., 2005). Individual applications of this model differ in the influence they ascribe to environmental factors, the scaling from leaf to ecosystem and the way how the model is assigned to different PFTs. The simple vegetation model used in this study is based on the equations derived by Cowan (1977) and Farquhar et al. (1980). The model includes responses of photosynthesis and transpiration to air temperature,

Table 1

Parameters used in the photosynthesis and transpiration model. Values given are the default or initial* values within the model optimization.

Parameter	Description	Value
$v_{cm,25}$	Carboxylation capacity ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	100*
$j_{m,25}$	Electron transport rate, ($\mu\text{mol m}^{-2} \text{s}^{-1}$)	300*
α	Quantum yield (mol mol^{-1})	0.7*
λ	Water use efficiency (mol mol^{-1})	8000*
O	O_2 concentration (mbar)	210
T_{ref}	Reference temperature for photosynthesis (K)	298.15
$K_{c,25}$	Kinetic coefficient for CO_2 at T_{ref} (μbar)	460
$K_{o,25}$	Kinetic coefficient for O_2 at T_{ref} (mbar)	330
E_{kc}	Activation energy for CO_2 (J mol^{-1})	59,356
E_{ko}	Activation energy for O_2 (J mol^{-1})	35,948
E_{jm}	Activation energy for j_m (J mol^{-1})	45,000
E_{vcm}	Activation energy for v_{cm} (J mol^{-1})	58,520

photosynthetically active radiation, vapor pressure deficit and soil water content. The model parameters are assumed to represent the relationship between nutrients and vegetation characteristics, and the adaptation to local climatic conditions.

The main parameters in this model are $v_{cm,25}$, $j_{m,25}$, α and λ (Table 1). $v_{cm,25}$ is the rate of carboxylation mediated by the enzyme Rubisco, $j_{m,25}$ is the maximum potential electron transport rate and α is the quantum yield. λ defines the ratio between water loss (transpiration) and CO_2 assimilation (photosynthesis) as a function of stomatal conductance (g_s) as proposed in the optimality hypothesis which states that plants optimize their stomatal conductance to maximize photosynthesis for a given amount of transpiration (Cowan, 1977):

$$\lambda = \frac{\delta E / \delta g_s}{\delta A / \delta g_s} \quad (1)$$

This stomatal conductance model was successfully used to reproduce observed ecosystem carbon and water fluxes by Arneth et al. (2002, 2006), van der Tol et al. (2007, 2008), Mercado et al. (2009) and Schymanski et al. (2009). Schymanski et al. (2007) compared the use of this model with the stomatal conductance model of Leuning (1995) and concluded that both models performed equally well in reproducing observed transpiration rates. A complete model description with scaling from the leaf to the ecosystem scale and temperature responses is presented in Appendix A.

2.2. Observations

The Fluxnet database contains fluxes measured with the eddy covariance technique (Aubinet et al., 2000) at more than 200 locations worldwide. All data is processed in a harmonized manner within the Fluxnet project (Baldocchi et al., 2001; Baldocchi, 2008) as described by Papale et al. (2006), Reichstein et al. (2005), Moffat et al. (2007) and Papale and Valentini (2003). The data used here were retrieved from the database in April 2008.¹ A complete list of the sites used is given in Appendix B; Table 2 lists the PFTs used. These sites were selected based on data availability. To apply the model for photosynthesis (A) and transpiration (E) fluxes requires the following variables: Net Ecosystem Exchange (NEE), Latent Heat Flux (LE), vapor pressure deficit (VPD), air temperature (T_a), global radiation (R_g), leaf area index (LAI) and soil water content (θ). Sites with data gaps of more than 50% during the growing season or missing input variables were excluded from the analysis. The 101 selected sites contain 453 site years of which 349 years contain sufficient observations (not gap-filled) to simulate the fluxes. For 57 site years there were no LAI data available, mainly because there

Table 2
Number of Fluxnet sites used in this study within plant functional types as classes of vegetation and climate.

	Arctic	Boreal	Subtropical Mediterranean	Temperate	Temperate continental	Tropical	Total
Cropland			2	3			5
Closed shrubland			1				1
Deciduous broadleaf forest		2	6	6	4		18
Evergreen broadleaf forest			2	1		4	7
Evergreen needleleaf forest		17	9	10	4		40
Grassland	1		3	13			17
Mixed Forest			2	2	3		7
Open shrubland		1			1		2
Savanna			1			1	2
Wetland				1			1
Woody Savanna						1	1
Total	1	20	27	36	11	6	101

were no remotely sensed observations before 2000, and for 57 (different) site years soil water content data was unavailable.

LAI is derived from the MODIS database and is used as a proxy for phenology (ORNL DAAC, 2009). This database contains 8-day composite values of LAI for each site based on 7 km × 7 km data sets centered around the sites. From these pixels the average is calculated from observations with no clouds and no presence of snow or ice. The 8-day composites are linearly interpolated to determine daily values.

The observed carbon flux from eddy covariance represents the net exchange of carbon between ecosystem and atmosphere. The observed flux (F_c) plus a term representing storage within the vegetation is assumed to be equal to NEE . Nighttime NEE is assumed to be equal to ecosystem respiration (R_e). Within the Fluxnet database the observed NEE is partitioned into gross primary production (GPP) and R_e . R_e is determined from a temperature function of nighttime fluxes by using the methodology of Reichstein et al. (2005). In our study this GPP or photosynthesis flux is used.

The model requires the knowledge of the transpiration flux to estimate model parameters, whereas the observed water vapor flux (LE) is the sum of transpiration and soil evaporation. However, the latter contributes little to total evaporation when the soil surface is dry, or when $LAI > 2.5$, because then little energy is available for evaporation. It was thus assumed that total evaporation equals transpiration when the vegetation is dry, and these periods were selected by excluding data during days with precipitation and 3 days thereafter. Using data for several sites showed that estimates of model parameters remained constant with removal of data after rainfall for 3 or more days.

2.3. Model parameter estimation

The model is optimized using the simplex search method (Lagarias et al., 1998). A least squares objective function, or normalized root mean square error is minimized to give the optimal model parameters. This is a multi-criteria problem with both photosynthesis and transpiration being parameterized, therefore the objective function consists of two parts. The normalized root mean square errors ($RMSE_n$) derived from half-hourly observations of the two fluxes are added, giving equal weight to both processes:

$$RMSE_n = \frac{\sqrt{(\sum (A_{sim} - A_{obs})^2)/N}}{\overline{A_{obs}}} + \frac{\sqrt{(\sum (E_{sim} - E_{obs})^2)/N}}{\overline{E_{obs}}} \quad (2)$$

where A_{sim} is simulated photosynthesis, A_{obs} daytime GPP , E_{sim} simulated transpiration and E_{obs} observed transpiration. The model parameters were derived for all sites within the Fluxnet database or for different groups of site years classified by vegetation type and climate.

2.4. Grouping sites based on model parameters

The deductive classification is based on an understanding of processes that determine the functioning of vegetation (Woodward and Cramer, 1996). One example is the classical grouping of sites into vegetation classes (Table 2). Inductive classification groups are directly derived from sets of observations. This approach can be applied with statistical clustering. Here we use the model parameters to group the sites. This is a combination of the two classifications, because derived parameters and not the direct observations are used to classify the sites.

Two statistical methods are used and compared, hierarchical and k -means clustering. Hierarchical clustering groups data by creating a cluster tree or dendrogram. The tree is a multilevel hierarchy, where clusters at one level are joined to clusters at the next level. k -means clustering partitions n observations into k clusters. Parameter values within each cluster are as close to each other as possible, but as far as possible from values in other clusters. The centre of each cluster is the point to which the sum of distances from all values in that cluster is minimized. The result is a set of clusters that are as compact and well-separated as possible (Seber, 1984). The MATLAB software package was used for both the optimization of the model and the analysis of the results.

3. Results

3.1. Evaluation of flux simulations

Half-hourly observations of fluxes and environmental variables were used to optimize the model with annual parameters. Five sets of parameters were derived: for all sites together (A), for groups of sites with a similar vegetation type (V), for groups of sites with a similar vegetation type and climate (VC), for individual sites (S) and for individual site years (SY). The quality of the simulations for these five parameter sets is presented for the diurnal, seasonal and annual time scales.

The average diurnal cycle in July derived from observations of photosynthesis (A) and transpiration (E) is compared with fluxes simulated with vegetation model parameters (V, Fig. 1) and fluxes simulated with model parameters of individual site years (SY, Fig. 2). Examples are presented for a tropical evergreen broadleaf forest in Brazil, a boreal evergreen needleleaf forest in Finland and a subtropical grassland in the US. The diurnal variation for these different locations is captured best with simulations that use site year parameters. When using vegetation parameters the fluxes are over- or underestimated (BR-Ban and FI-Hyy) or photosynthesis and transpiration start too late in the morning (US-Goo).

Fig. 1. Comparison of the observed and simulated average diurnal cycle of photosynthesis (left) and transpiration (right) in July for three different sites. The fluxes are simulated with parameters derived for all sites with a similar vegetation type (V, Table 3). The average observed fluxes with standard deviations are presented by the grey area and the average simulated fluxes with standard deviations by the black lines.

Fig. 2. Comparison of the observed and simulated average diurnal cycle of photosynthesis (left) and transpiration (right) in July for three different sites. The fluxes are simulated with parameters derived for each site year (SY). The average observed fluxes with standard deviations are presented by the grey area and the average simulated fluxes with standard deviations by the black lines.

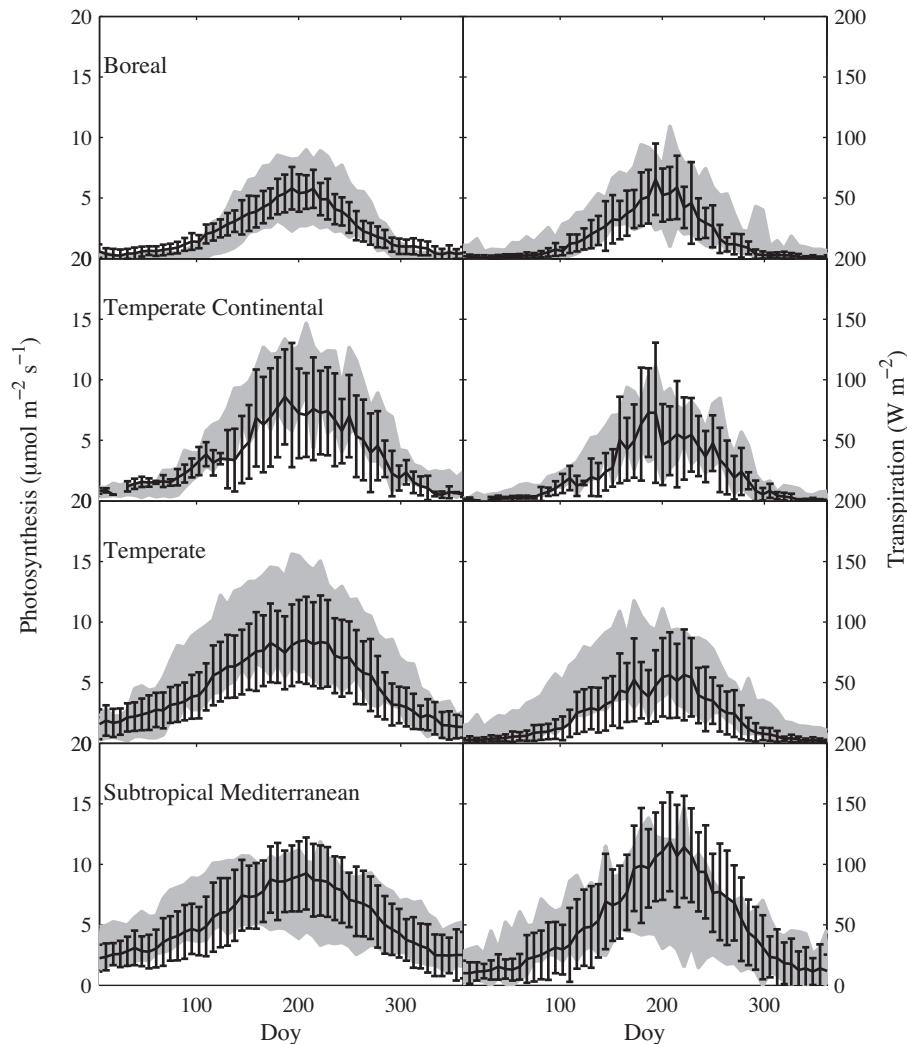

Fig. 3. Seasonal variation of the average weekly observed and simulated photosynthesis (left) and transpiration (right) for the evergreen needle leaf forest sites in four different climates. The fluxes are simulated with parameters derived for all sites with a similar vegetation type and climate (VC, Table 4). The average observed fluxes with standard deviations are presented by the grey area and the average simulated fluxes with standard deviations by the black lines.

Observed and simulated average seasonal cycles of A and E and their standard deviations are shown in Figs. 3 and 4 for evergreen needleleaf forest (ENF) sites growing in four climatic zones. A comparison is made between fluxes simulated with PFT model parameters as in Table 4 (VC) and fluxes simulated with model parameters of individual site years (SY). The average seasonal cycle of simulated A and E of boreal ENF sites is comparable to the observations in both figures. Standard deviations are only correct when using the site year parameters, fluxes simulated with PFT parameters show too little variation. For temperate continental and temperate ENF sites fluxes simulated with PFT parameters are underestimated, while the simulations using site year parameters show a seasonal variation, which is closer to the observations. In the subtropical and Mediterranean regions the fluxes are overestimated in both figures, particularly during summer.

Annual simulated fluxes are compared with observations in Fig. 5. The coefficients of determination (r^2) for annual A and E range from 0.39 to 0.93. The deviation between observations and simulations increases when using more general model parameters, which are derived for larger groups of sites. Simulations using vegetation parameters (V) or PFT parameters (VC) instead of one single parameter set (A) show only very minor improvements. Simulated fluxes are of a higher quality only when model parameters of indi-

vidual sites (S) or site years (SY) are used. A simplification with less variation in model parameter values results evidently in poorer simulations with deviations of both the diurnal and seasonal cycles resulting in over- or underestimation of annual fluxes.

3.2. Model parameter variation within and across vegetation types

Fig. 6 shows that the mean parameter values and their standard deviations can differ considerably for each vegetation type depending on how the data are classified. For example, the mean values of $v_{cm,25}$ and λ systematically increase for cropland, savanna and evergreen needleleaf forest vegetation types as the data are segregated according to vegetation type (V), vegetation and climate (VC), sites (S) or site-years (SY). While it is difficult to discern systematic trends in other parameters and for other vegetation classes, the different classifications do not strongly affect the relative ranking of parameter values, e.g. the highest values of $v_{cm,25}$ are for croplands and the highest λ for savannas. For each vegetation type in Fig. 6 an average of different parameter sets is presented. The vegetation parameters (V) are derived for all sites within a group, and therefore do not have a standard deviation. The PFT parameters (VC) are derived with climates within a vegetation type as in Table 4, the site

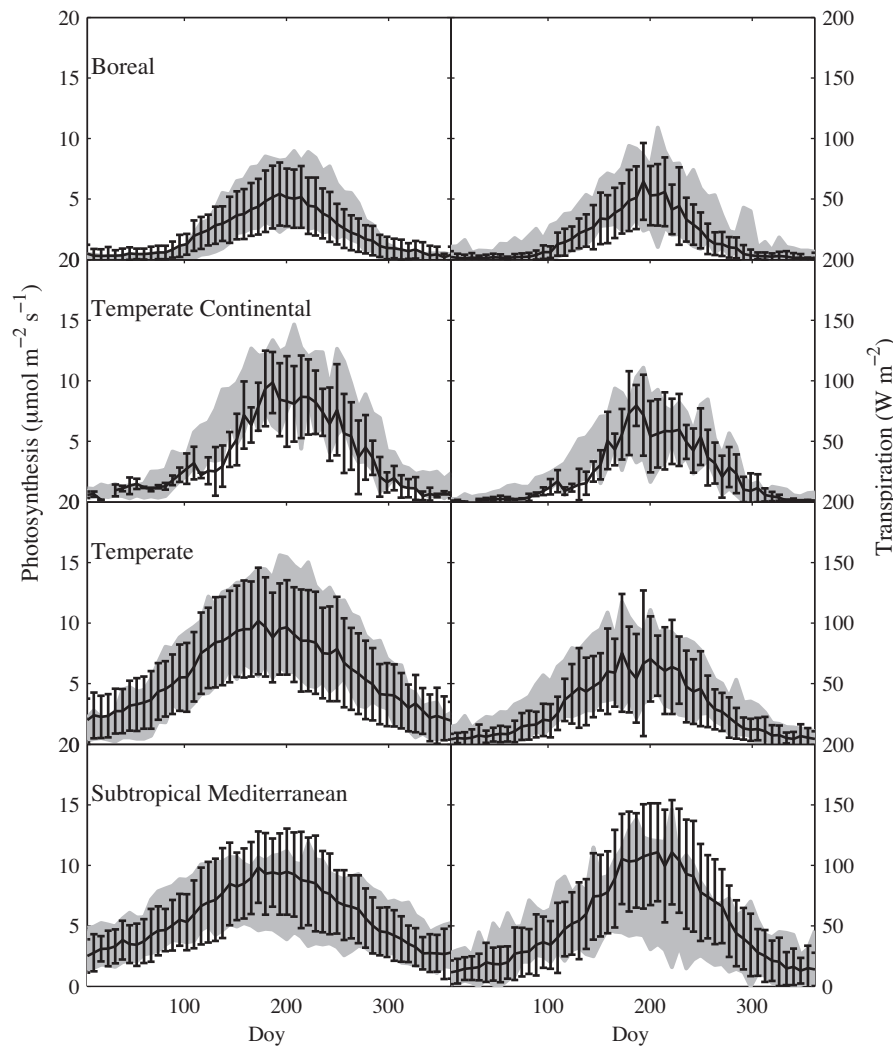

Fig. 4. Seasonal variation of the average weekly observed and simulated photosynthesis (left) and transpiration (right) for the evergreen needle leaf forest sites in four different climates. The fluxes are simulated with parameters derived for each site year (SY). The average observed fluxes with standard deviations are presented by the grey area and the average simulated fluxes with standard deviations by the black lines.

parameters (S) with all sites as in Table 2 and the mean site year parameter (SY) with all years as in Table 3. The different number of parameters within each group will influence the standard deviations and thus their means and standard deviations cannot directly be compared.

The standard deviation (σ) of the parameter values from all site years is an indicator for the variation within a group. With σ the 95% interval confidence intervals in Tables 3 and 4 are estimated. First the standard error is calculated ($\sigma_M = \sigma / \sqrt{p_1} \sqrt{n}$), which is used to determine the 95% intervals ($p_2 \pm 1.96\sigma_M p_2$), assuming that the parameters are normally distributed. \bar{p}_1 is the mean of the site year parameters within a group and p_2 the parameter derived for the group. Cropland parameters have high values for $\nu_{cm,25}$ and α and

a low λ (more efficient water use) (Table 3). This implies that crops are more efficiently assimilating carbon in comparison to other (natural) vegetation types. In contrast, the parameters for savanna, which includes a mixture of grassland, trees and shrubs, imply a low photosynthetic productivity with a high λ . The different forest types show very similar parameter values. The main difference between deciduous and evergreen broadleaf forests is seen for λ , which implies a more efficient water use for the deciduous forests. The two types of evergreen forests show comparable high values for λ . Grassland has an even larger value for λ , while also $\nu_{cm,25}$ and $j_{m,25}$ are higher than for the different forests.

The quality of the flux simulations are improved only slightly by adding extra model parameters through differentiating vegeta-

Table 3

Model parameters with 95% confidence intervals derived for groups of site years (n) within seven vegetation classes. $\nu_{cm,25}$ and $j_{m,25}$ in $\mu\text{mol m}^{-2} \text{s}^{-1}$, α and λ in mol mol^{-1} .

	n	$\nu_{cm,25}$	$j_{m,25}$	α	λ
Cropland	12	48.6 ± 29.9	136.9 ± 33.2	0.27 ± 0.09	150.60 ± 124.8
Savanna	22	18.0 ± 9.7	68.4 ± 35.5	0.11 ± 0.02	593.34 ± 273.0

Grassland	55	43.3 ± 5.0	238.9 ± 31.0	0.10 ± 0.02	276.46 ± 75.4
Mixed forest	25	36.4 ± 11.0	136.2 ± 51.8	0.25 ± 0.05	149.80 ± 131.0

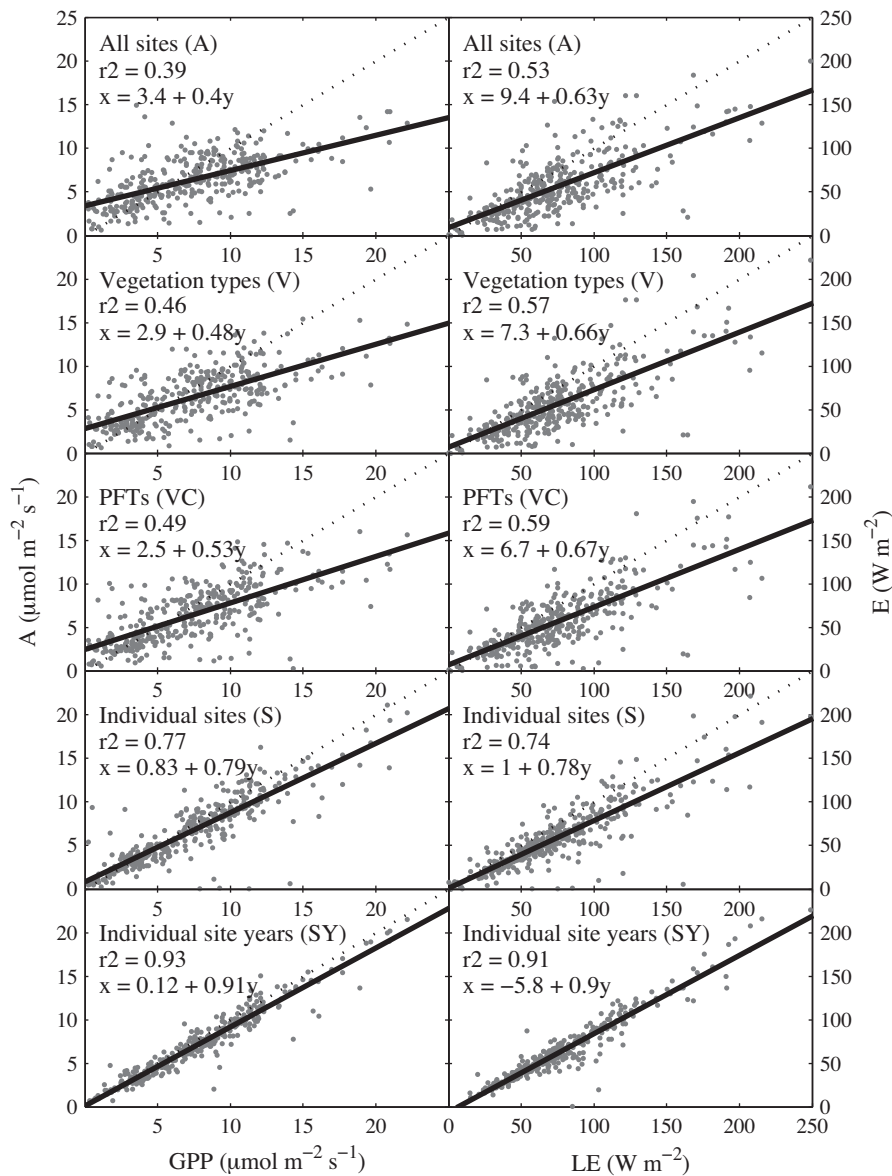

Fig. 5. Comparison of observed and simulated average annual photosynthesis and transpiration fluxes for all site years. Observed fluxes are *GPP* and *LE* and simulated fluxes are *A* and *E*. The dotted line is the 1:1 line and the solid line the regression line. Differences between the panels are the used parameters to simulate the fluxes derived for all sites together (top panels), for groups of sites with a similar vegetation type, for PFTs, for individual sites or for individual site years (lower panels).

tion classes according to climate (compare *V* to *VC* in Fig. 5). This could suggest that variation of model parameters is not related to climate. In Table 4 the parameters for groups of sites with similar vegetation type and climate (PFTs) are presented to verify this. From this table it is not instantly clear whether a systematic difference exists between climate sub-groups within a PFT. For instance, $v_{cm,25}$ is similar for the climates of evergreen needleleaf forest sites, but variable for the climates of deciduous broadleaf forest sites.

3.3. Grouping sites based on model parameters

Variation of model parameters between PFTs is not coherent (Table 4). The use of this classification results in incorrect simulated fluxes (Fig. 5). Therefore we will attempt to define an independent classification purely based on the model parameters. Hierarchical clustering and *k*-means clustering are both used to group site years with comparable model parameter sets. The choice of the number of groups is subjective, but we chose seven, the same as the number of vegetation types. Different numbers of groups were also

tested and these produced comparable results. From Table 5 it can be seen that one large group with 175 site years, and six smaller groups were distinguished when using hierarchical clustering. For *k*-means clustering the groups are more evenly distributed (Table 6). Because the two clustering methods are very sensitive to outliers only those site years are used that are within the range as presented in Fig. 7. Although the groups derived with the two clustering methods are not the same, the patterns as in Fig. 7 are almost identical (data not shown), and thus only the results of *k*-means clustering are discussed further. In Fig. 7 the distribution of the different sites and groups within the parameter space is shown. As expected the groups are clustered around central means. From this figure also the relations between parameters can be seen. For instance, the ratio between $v_{cm,25}$ and $j_{m,25}$ is assumed to be constant in many models. Here both parameters are derived and this results in a ratio of 3.60 ± 1.51 at 25°C , which is higher than for instance the ratio of 2.0 ± 0.60 as derived by Leuning (2002) from 43 data sets. The parameters $j_{m,25}$ and α are closely linked in Eq. 8, which could result in equifinal simulated fluxes with multiple parameter

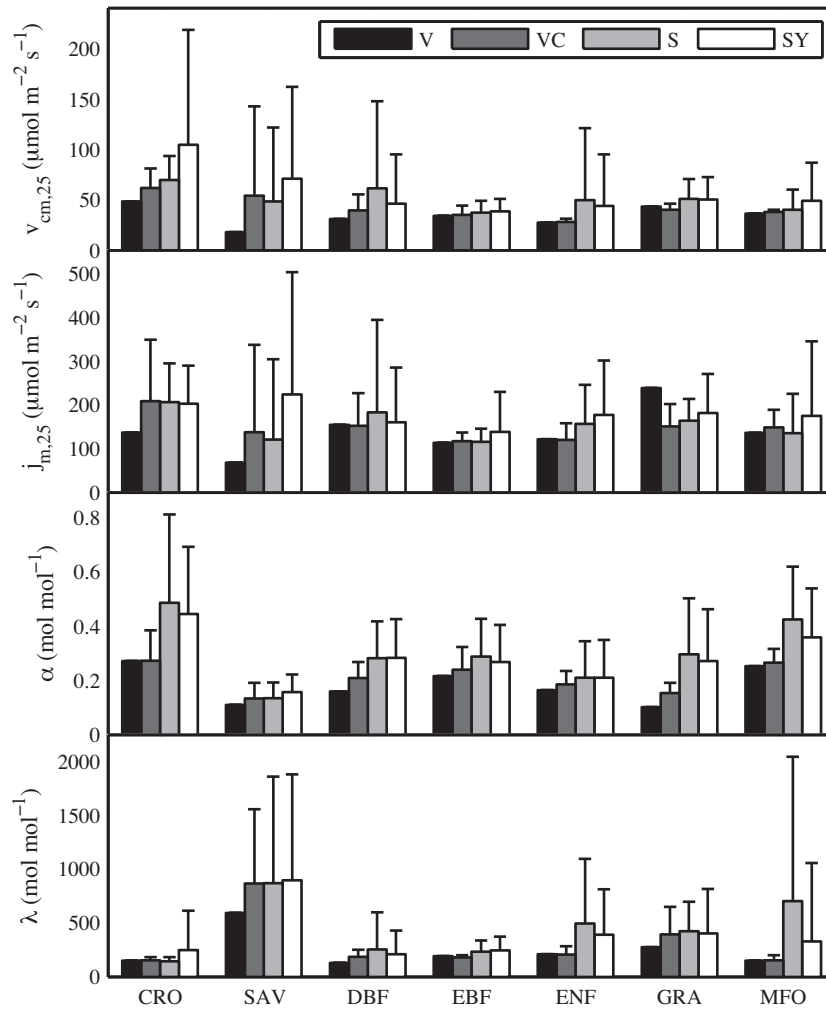

Fig. 6. Mean model parameters and standard deviations for seven vegetation types (as in Table 3) derived for groups of sites with a similar vegetation type (V), for PFTs (VC), for individual sites (S) or for individual site years (SY).

sets. For group 4 this might be occurring, with low values for α and high values for $j_{m,25}$.

Vegetation type and climate region are not driving factors behind the classification. Each group, derived by *k*-means clustering, contains almost all vegetation types and climate regions within the different groups. Evergreen broadleaf forests are only found in the first three groups, which contain all different climate regions. Groups 4 and 5 both consist of evergreen needleleaf forests and grasslands in boreal and temperate regions. The differences between these groups are a high $j_{m,25}$ and a low λ for group 4, and a low $j_{m,25}$ and a high λ for group 5.

4. Discussion

In global land-surface models parameters are distributed by PFTs (Bonan et al., 2003; Sitch et al., 2003; Krinner et al., 2005). For instance, bioclimatic limits are chosen defining the possibilities for establishment and survival of a given PFT at a certain location, or a temperature response of photosynthesis. We suggest with our findings that model parameters are more variable than are assumed within given PFTs. This finding is supported by statistical grouping of the sites based on the model parameter values. The derived groups could not be related to vegetation type or climate region (Fig. 8). Site years with comparable model parameters do not have a common vegetation type or climate.

This raises the question of what the common characteristics are for these statistically determined groups of sites. These characteristics are essential to provide parameter values for every grid cell in a global land-surface model. One possible hypothesis poses that the parameters are a representation of short term strategies to avoid stress and responses to disturbances to for example drought, heat or a lack of nutrients (Bonan et al., 2003). With this concept differences between the statistical groups may be better understood. The variation will not be detectable when comparing average environmental variables, because in almost all cases stress occurs only during specific short periods. A second possible hypothesis poses that sites cannot be grouped based on the model parameters. PFTs might be changing too abruptly, while in reality the drivers cause a more gradual change. A classification of vegetation can be following these more gradual transitions, comparable to the leaf economics spectrum (Reich et al., 1997; Wright et al., 2004; Harrison et al., 2010). Alternatively, our simple model formulations may not be able to capture the variation of processes involved in the global ecosystem carbon and water balance. This could potentially also result in a too large parameter variation within a PFT, that would be an artifact of the modeling approach rather than a real phenomenon. While we think this explanation is rather improbable, we cannot completely discard it either with the current analysis.

The finding that model parameters are more variable than are assumed with the PFTs is supported by the quality of the simulated fluxes, which increases with more specifically defined model

Table 4
Model parameters derived for groups of site years (n) of the PFTs from Table 2. $v_{cm,25}$ and $j_{m,25}$ in $\mu\text{mol m}^{-2} \text{s}^{-1}$, α and λ in mol mol^{-1} . * invalid value of α resulted in incorrect parameters. ** unable to derive confidence intervals due to small sample size.

parameters (Fig. 5). The acceptance of the quality of flux simulations using PFT model parameters in global models depends on the purpose of the simulations. It will be quite different if we want to model a given site to a high degree of precision and accuracy or whether we want a global model to work with prescribed accuracy with a minimum number of parameters.

The quality of the flux simulations and the values of the model parameters are influenced by the quality of the data used and by the model structure. Flux measurements contain random and systematic errors. Random errors result from the equipment used and data processing procedures, such as inaccurate calibrations, high- and low-frequency flux losses. Systematic errors occur because of

storage-related problems during low turbulence conditions and advection (Raupach et al., 2005; Richardson et al., 2006, 2008; Lasslop et al., 2008). The model parameters in this study are optimized with eddy covariance flux data and given meteorological data. Parameter uncertainty derived from these observations has been determined by Richardson et al. (2007) – around 5–15% for the parameters of their model – and are comparable between years. The mean absolute weighted error was used to estimate maximum likelihood parameters in their study, because the flux error is approximated by a double-exponential distribution (Richardson and Hollinger, 2005). But according to Lasslop et al. (2008) the flux error distribution follows a superposition of Gaussian distributions. They tested different objective functions, and concluded that there were no significant differences between the least squares optimization with the use of absolute deviations. We use gross primary production (GPP) fluxes from the Fluxnet database, which are derived from observed NEE by a simple model (Reichstein et al., 2005). This could introduce an additional uncertainty into our results, because we use this flux to derive photosynthesis parameters.

A critical part of the model structure is the upscaling from leaf to ecosystem model parameters based on LAI . We use satellite derived values of LAI , which is for most sites a representation of a larger area than covered by the eddy covariance flux footprint. Especially when the vegetation representation of the two observations are not in agreement errors will be introduced. In the subtropical Mediterranean region the fluxes are overestimated, particularly during summer. This is a result of the use of annual model parameters which are scaled with LAI , which may not be able to describe structural adaptation of vegetation to drought. The poor quality of the simulated fluxes for the savanna sites may be attributed to the fact that this vegetation type consists of a combination of grasslands and trees, with different vegetation characteristics that cannot be scaled up with one single value for LAI . This problem has an impact on the variation of model parameters. Further work is needed to quantify this impact, and to investigate other possibilities for the upscaling from leaf to ecosystem.

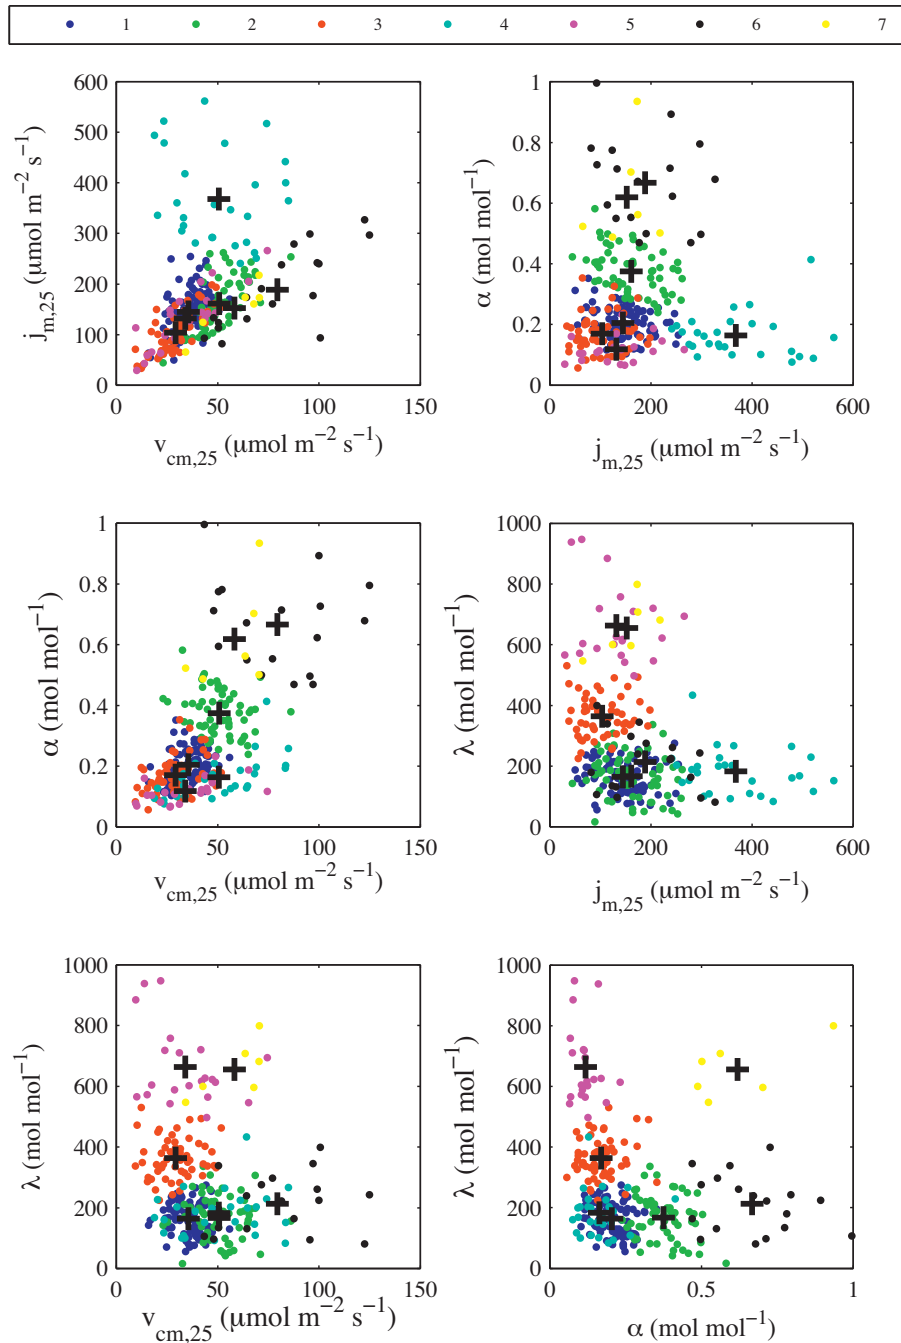

Fig. 7. Model parameters classified by k -means clustering. Each point represents a site year, the colors represent different groups and the black crosses represent averages for each group.

The results of our study can only be compared with other studies when taking into account the differences between the model formulations. The values of $v_{cm,25}$ derived by Medlyn et al. (2002b) from measurements on needles from a forest in France are within the same range as the values we derived for needleleaf forests. $v_{cm,25}$ can be compared, because a similar temperature response is used (Eq. 23), although we keep E_{vcm} constant. We assumed a constant temperature response, but Medlyn et al. (2002b) observed a seasonal variation. They compared values of $v_{cm,25}$ and $j_{m,25}$ and found that values were highest for crops and comparable for deciduous and evergreen trees. We derived this variation from the eddy covariance observations. The values derived from the fluxes by Thum et al. (2008) for three forests in Finland and Sweden and

by Verbeeck et al. (2008) for a temperate deciduous forest are similar to our results. It is interesting to note here that with both a bottom-up and top-down approach comparable parameter values are derived.

The water use efficiency (λ) is not as frequently used as the parameters from the model of Farquhar et al. (1980). From the definition of λ , given in Eq. 1, it can be seen that a higher λ indicates a lower water use efficiency. Arneth et al. (2006) use the terms conservative and aggressive water use for low and higher values of λ for sites in Siberia and southern Africa. This is what our results show as well, with highest values of λ for the savanna sites. These results are interesting, as the lowest values of λ would be expected at the site with largest water stress. This is consistent with the results of

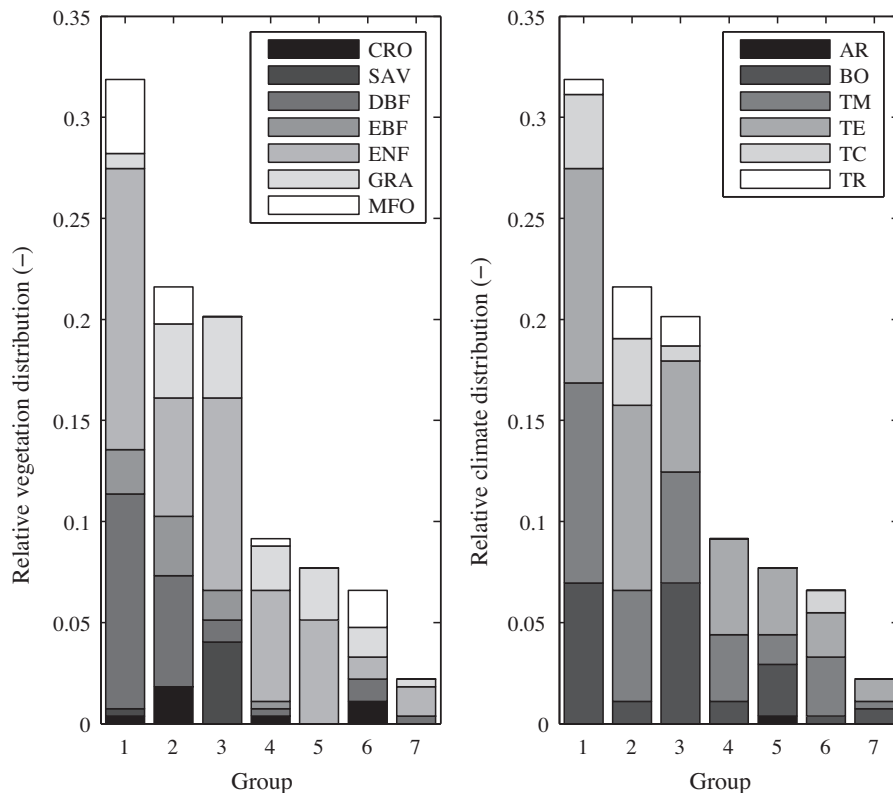

Fig. 8. Distribution of vegetation types and climate regions within groups in Table 6 derived from *k*-means clustering for Model I. Vegetation types are cropland (CRO), savanna (SAV), deciduous broadleaf forest (DBF), evergreen broadleaf forest (EBF), evergreen needleleaf forest (ENF), grassland (GRA) and mixed forest (MFO). Climates are arctic (AR), boreal (BO), subtropical Mediterranean (TM), temperate (TE), temperate continental (TC) and tropical (TR).

Schymanski et al. (2009), who derived a low value for λ during the dry season and higher values during the wet season for a savanna site in Australia.

5. Summary and conclusions

With a simple photosynthesis model we derived parameters for all sites available within the Fluxnet database. The model is capable of simulating the diurnal and seasonal variation of photosynthesis and transpiration fluxes for a large range of sites with different vegetation types and climates. For this no additional site information is needed besides the eddy covariance fluxes, meteorological data and seasonal *LAI*, the simplified approach allowing us to apply the model at all sites.

The choice of a parameter classification has a large impact on the quality of the simulated photosynthesis and transpiration fluxes. When more general parameters are used, the quality of the fluxes decreases. The diurnal and seasonal cycles and annual average fluxes are over- or underestimated. The best fluxes are simulated with parameters that are derived for each individual site year. This indicates that a PFT classification introduces an uncertainty to the short term variation of photosynthesis and transpiration fluxes.

We conclude that model parameters are more variable than assumed with the PFTs. A PFT classification does not reflect reality of short term photosynthesis and transpiration flux variation, supporting that a more dynamic description of trait-based PFTs is a necessary next step. Site years with comparable model parameters do not have a common vegetation type or climate. The derived groups could not be related to vegetation type or climate region. Although site year parameters produce the best results, this generates a different problem. The parameters are too specific to be used

in a global study, but they can be used to explore the possibilities of an alternative classification scheme. The question as to whether it is possible to classify sites, or if a more fine scaled methodology with gradual transitions is needed is still open. Further work is needed before a classification of vegetation within a global climate model can be produced.

This research is funded by a grant from the Netherlands Organization for Scientific Research (NWO).

Appendix A. Model description

A.1. Photosynthesis and transpiration

Photosynthesis is simulated with a biochemical model based on the work of Farquhar et al. (1980). Leaf photosynthesis (A) is the minimum of carboxylation (W_c) and Ribulose-1,5-bisphosphate (RuBP) regeneration (W_j) minus respiration (R_d).

$$A = \left(1 - \frac{\Gamma^*}{C_i}\right) \min\{W_c, W_j\} - R_d \quad (3)$$

where Γ^* is the compensation point for CO_2 in absence of dark respiration (bar) and C_i the intercellular partial pressure of CO_2 (bar) and $R_d = 0.07V_{cm}$. W_c and W_j are determined with the following equations (Farquhar et al., 1980; von Caemmerer and Farquhar, 1981):

$$W_c = \frac{V_{cm}C_i}{C_i + k'} \quad (4)$$

$$W_j = \frac{JC_i}{4(C_i + 2\Gamma^*)} \quad (5)$$

$$k' = K_c(1 + O/K_o) \quad (6)$$

$$\Gamma^* = 0.5 \frac{V_{om} K_c}{V_{cm} K_o O} \quad (7)$$

$$J = \frac{\alpha I_{PAR} J_m}{\alpha I_{PAR} + 2.1 J_m} \quad (8)$$

where I_{PAR} is the photosynthetic active radiation ($\mu\text{mol photons m}^{-2} \text{s}^{-1}$), J the electron yield, V_{cm} the rate of carboxylation mediated by the enzyme Rubisco ($\mu\text{mol m}^{-2} \text{s}^{-1}$), V_{om} the rate of oxygenation of Rubisco ($\mu\text{mol m}^{-2} \text{s}^{-1}$), J_m the maximum potential electron transport rate ($\mu\text{mol m}^{-2} \text{s}^{-1}$), α the quantum yield (mol mol^{-1}), K_c the kinetic coefficient for CO_2 (bar), K_o the kinetic coefficient for O_2 (bar) and O the partial pressure for O_2 (bar). The ratio V_{om}/V_{cm} is assumed to be a constant of 0.21.

The reduction of photosynthesis when soil water is limited, is simulated by multiplying the right hand side of Eq. 3 by a factor β , which ranges between 0 and 1 (Matsumoto et al., 2008):

$$\beta = \frac{(\theta - \theta_{\min})(\theta_{\max} - \theta_{\min} + \beta_1)}{(\theta_{\max} - \theta_{\min})(\theta - \theta_{\min} + \beta_1)} \quad (9)$$

$$A = \beta[(1 - \Gamma^*/c_i) \min\{W_c, W_j\} - R_d] \quad (10)$$

where θ is the soil water content (%), θ_{\min} and θ_{\max} are the minimum and maximum volumetric soil water content observed at a site and β_1 is a parameter used to fit an envelope curve around the soil water content observations. With β both photosynthesis and transpiration are reduced during dry periods.

Transpiration (E) is a function of stomatal conductance (g_s), which can be calculated from A , c_a and c_i (ppm):

$$g_s = \frac{A}{c_a - c_i} \quad (11)$$

$$E = 1.6Dg_s \quad (12)$$

where D is the molar vapor gradient between stomata and the air and 1.6 the ratio of molecular diffusivity of H_2O to CO_2 .

The internal partial pressure of CO_2 (c_i) is determined as described by Arneth et al. (2002), where the models of Cowan (1977) and Farquhar et al. (1980) are combined, by solving the following quadratic equation:

$$k_2 C_i^2 + k_1 C_i + k_0 = 0 \quad (13)$$

There are two sets of solutions for the k parameters, under enzyme-limited conditions (W_c) and light-limited conditions (W_j). In the

enzyme-limited case the values for the k parameters are calculated with the following equations:

$$k_2 = \lambda - \frac{1.6D}{k' + \Gamma^*} \quad (14)$$

$$k_1 = 1.6D - 2\lambda C_a + \frac{1.6D(\Gamma^* - k')}{k' + \Gamma^*} \quad (15)$$

$$k_0 = (\lambda C_a - 1.6D)C_a + \frac{1.6D\Gamma^*k'}{k' + \Gamma^*} \quad (16)$$

and in the light-limited case by:

$$k_2 = \lambda - \frac{1.6D}{3\Gamma^*} \quad (17)$$

$$k_1 = 1.6D - 2\lambda C_a - \frac{1.6D\Gamma^*}{3\Gamma^*} \quad (18)$$

$$k_0 = (\lambda C_a - 1.6D)C_a + \frac{1.6D2\Gamma^{*2}}{3\Gamma^*} \quad (19)$$

where C_a is the partial pressure of ambient CO_2 (bar) and λ the ratio between E and A as a function of g_s (mol mol^{-1}).

A.2. Scaling up from leaf to canopy

In most models scaling up is based on the assumption that the profile of leaf nitrogen content along the depth of the canopy follows the time-mean profile of radiation (Sellers et al., 1992; Arora, 2002). The main assumption is that the photosynthetic properties of leaves acclimate fully to the light conditions within a canopy. The photosynthetic capacity is proportional to the time-integrated absorbed radiation (Kull and Jarvis, 1995). Photosynthetically active radiation (PAR) is assumed to be the only variable determining change in the values of parameters within the canopy. The exponential light interception model holds:

$$I(x) = I_0 \times e^{-kL(x)} \quad (20)$$

where I_0 is the PAR incident on top of the canopy, $L(x)$ is the leaf area index cumulated from the top of the canopy down to level x , $I(x)$ is the PAR at level x within the canopy and k is a function of the leaf inclination angle distribution. Total PAR absorbed by the canopy (I_C) can be obtained by integrating Eq. 20 over the depth of the canopy, which results in:

$$I_C = I_0 \times \frac{(1 - e^{-kL})}{k} \quad (21)$$

Parameters that determine the photosynthesis rate follow the same exponential function. This implies that these parameters can be scaled up from the leaf to the canopy in a similar way (Cox et al., 1998; Wolf et al., 2006):

$$P = p \times \frac{(1 - e^{-kL})}{k} \quad (22)$$

where P is the canopy scale parameter and p the leaf scale parameter. This function applies for the canopy scale parameters V_{cm} , J_m and α_c which are derived from the temperature corrected parameters at the leaf scale (v_{cm} , j_m and α). k is set to 0.5 for all sites. λ is not scaled with LAI as it is parameterized on the ecosystem scale.

A.3. Temperature responses

At the leaf scale there are several studies in which the temperature response of v_{cm} and j_m are determined from observations (Bunce, 2000; Medlyn et al., 2002a,b; Kattge and Knorr, 2007). The parameters are described by an Arrhenius function or modified Arrhenius function with an optimal temperature. These different models have been validated at the leaf scale, but at the ecosystem scale there are no observations as the parameters are the sum of

the individual leaves. The temperature response function that will be used in this study is (Knorr and Kattge, 2005; Thum et al., 2008):

$$p = p_{25} \times \exp \left\{ \frac{E_p(T - T_{ref})}{T_{ref}RT} \right\} \quad (23)$$

This function applies for the parameters v_{cm} , j_m , K_C and K_O , for which $v_{cm,25}$, $j_{m,25}$, $K_{C,25}$ and $K_{O,25}$ are the parameter values at the refer-

ence temperature ($T_{ref} = 25^\circ\text{C}$), $E_{v_{cm}}$, E_{j_m} , E_C and E_O the activation energies, T the temperature [K] and R the gas constant.

Appendix B. Characteristics of the Fluxnet sites used in this study

See Table B.1.

Table B.1

The site name codes are a composition of country (first two letters) and site name (last three letters). Vegetation types are closed shrubland (CSH), cropland (CRO), deciduous broadleaf forest (DBF), evergreen broadleaf forest (EBF), evergreen needleleaf forest (ENF), grassland (GRA), mixed forest (MFO), open shrubland (OSH), savanna (SAV), wetland (WET) and woody savanna (WSA). Climates are arctic (AR), boreal (BO), subtropical Mediterranean (SM), temperate (TE), temperate continental (TC) and tropical (TR). References are given describing the sites, when no reference was available the site researcher is named.
